1 Behind the Torch of Life

1.1 Bioenergetics and Thermodynamics

Bioenergetics is the quantitative study of energy transductions. Of particular interest is the second law of thermodynamics.

Definition 1.1 (The second law of thermodynamics). *The Second Law of Thermodynamics states that the total entropy of an isolated system can never decrease over time. Isolated systems spontaneously evolve toward thermodynamic equilibrium, the state with the **maximum entropy**.*

In a **chemical reaction** entropy increases when the products of the reaction are less complex and more disordered than its substrates. Therefore in many biochemical reactions seem to contradict the second law as they "produce order"

To compensate the produced order by cells in their growth and division **free energy** is taken from the environment (organisms are not an isolated system) in the form of nutrients or solar light and exchanged for heat and entropy.

Definition 1.2 (Enthalpy, H). *Enthalpy (H) is the heat content of the reacting system. It reflects the number and kinds of chemical bonds in the reactants and products. When a chemical reaction releases heat, it is said to be exothermic; the heat content of the products is less than that of the reactants and ΔH has, by convention, a negative value. Reacting systems that take up heat from their surroundings are endothermic and have positive values of ΔH .*

Definition 1.3 (Entropy, S). *Entropy is a quantitative expression for the randomness or disorder in a system. When the products of a reaction are less complex and more disordered than the reactants, the reaction is said to proceed with a gain in entropy.*

Definition 1.4 (Free energy (G)). *It represents the energy available to do biological work, such as muscle contraction, active transport, and biosynthesis. The change in Gibbs free energy (ΔG) for a reaction is given by:*

$$\Delta G = \Delta H - T\Delta S$$

In biochemistry, Gibbs free energy (G) determines whether a metabolic reaction "can occur spontaneously" (but may still be unlikely because of TS) in living systems. A process is favorable if it is **Exergonic Reaction**, $\Delta G < 0$.

An important property is that variations in delta G are **additive**:

$$\Delta G_{\text{total}} = \Delta G_1 + \Delta G_2$$

This property lets us **make unfavorable reaction favorable when coupling them to a highly favorable reaction**. This is explored by various biological pathways.

Remark 1.5 (Standard transformed constants). Physical constants based on this biochemical standard state are called **standard transformed constants** and are written with a prime (such as $\Delta G'^{\circ}$ and K'_{eq}) to distinguish them from the untransformed constants used by chemists and physicists.

1.1.1 Equilibrium

By the second law of Thermodynamics, a reaction continues until equilibrium, the maximal entropy is reached. This is described by the **equilibrium constant** (K) that quantifies the ratio of **product over reactant** concentrations at equilibrium. It is defined for a general reaction:

$$K = \frac{[C]^c[D]^d}{[A]^a[B]^b}$$

$$\Delta G^\circ = -RT \ln K$$

Remark 1.6 (steady state). In biological process the equilibrium is practically never reached. Nevertheless the system reaches a steady state, where the the concentrations stays constant thanks to a net flow equal to zero.

1.1.1.1 Reaction Quotient

The **Reaction Quotient** is similar to the equilibrium constant, but it uses the actual, observed concentrations of reactants and products, rather than the equilibrium concentrations. Q is defined as:

$$Q = \frac{[C]_{\text{obs}}^c [D]_{\text{obs}}^d}{[A]_{\text{obs}}^a [B]_{\text{obs}}^b} \quad (1)$$

$$\Delta G = \Delta G^\circ + RT \ln Q \quad (2)$$

1.1.1.2 Mass Action Ratio (Q/K)

The **Mass Action Ratio** is the ratio of the reaction quotient (Q) to the equilibrium constant (K). The mass action ratio helps us understand **where a reaction is going**:

$$\Delta G = RT \ln \frac{Q}{K} \quad (3)$$

- If $Q/K < 1$, then $\Delta G < 0$, and the reaction will proceed in the forward direction to reach equilibrium.
- If $Q/K > 1$, then $\Delta G > 0$, and the reaction will proceed in the reverse direction to reach equilibrium.
- If $Q/K = 1$, then $\Delta G = 0$, and the reaction is at equilibrium.

1.1.1.3 Henderson-Hasselbach

Since in a biological context the environment is buffered at near-constant pH, the Henderson-Hasselbach equation is generally applicable to determine the ratio of the different protonation states of a compound.

$$\text{pH} = \text{pKa} + \log \left(\frac{[\text{A}^-]}{[\text{HA}]} \right)$$

1.2 Back to OCI

The reactions that do occur in cells represent a toolbox that evolution has used to construct metabolic pathways that circumvent the “impossible” reactions. Most of the reactions in living cells fall into one of five categories:

- reactions that make or break carbon–carbon bonds
- internal rearrangements, isomerizations, and eliminations
- free-radical reactions
- group transfers
- oxidation-reductions

Remark 1.7 (Covalent Bond). A covalent bond consists of a shared pair of electrons, and the bond can be broken in two general ways. In **homolytic cleavage**, each atom leaves the bond as a radical, carrying one unpaired electron. In **heterolytic cleavage** which is more common, one atom retains both bonding electrons.

Remark 1.8 (Nucleophiles and Electrophiles). Nucleophiles (functional groups rich in and capable of donating electrons) and electrophiles (electron-deficient functional groups that seek electrons).

1.2.0.1 Reactions that make or break carbon-carbon bonds

Heterolytic cleavage of C-C bonds yields a carboanion and a carbocation. Conversely, the formation of a C-C bond involves the combination of a nucleophilic carboanion and an electrophilic carbocation. *Note, that carboanions and carbocations are generally so unstable that their formation as reaction intermediates can be energetically impossible even with the help of an enzyme.*

Therefore these reactions need assistance by functional groups containing electronegative atoms (O and N). This can alter the electronic structure of adjacent carbon atoms (**carbonyl-groups**, withdrawing electrons), stabilizing and facilitating the formation of carboanion and cation intermediates. *This can be further enhanced by the presence of metal ions such as Mg^{2+} for example.*

Aldol condensation is a common way to create C-C bonds, i.e. the aldolase reaction which converts six-carbon compounds to three-carbon compounds in glycolysis is an aldol condensation in reverse.

In a **Claisen condensation**, the carbanion is stabilized by the carbonyl of an adjacent thioester; an example is the synthesis of citrate in the citric acid cycle. Sometimes imine or certain cofactors play the role as the "electron-withdrawer".

Figure 1: make or break carbon-carbon bonds

1.2.0.2 Internal rearrangements, Isomerizations, and Eliminations

In this type of reactions **electrons are redistributed altering the bonding framework** without changing the overall oxidation state of the molecule. For example different groups undergo oxidation-reduction leading to **cis-trans rearrangements** or shifting the **position of double bonds**, i.e. formation of glucose 6-phosphate in glycolysis. Here C1 is reduced and C2 is oxidized.

Figure 2: Isomerization and elimination reactions

An example for an **elimination** reaction is the loss of water from an alcohol resulting in a double $C=C$ bond. *Similar reaction can result from eliminations in amines.*

1.2.0.3 Free-Radical Reactions

The homolytic cleavage of covalent bonds generates free radicals. These radicals can then trigger other reactions.

Figure 3: A free radical-initiated decarboxylation reaction

1.2.0.4 Group Transfer Reactions

The transfer of acyl, glycosyl, and phosphoryl groups from one nucleophile to another is common in living cells. Acyl group transfer generally involves the addition of a nucleophile to the carbonyl carbon of an acyl group to form a tetrahedral intermediate.

A general idea in metabolism is to attach a good leaving group to a metabolic intermediate to trigger subsequent reactions. Since nucleophilic substitutions are made more favorable by the attachment of a phosphoryl group to an otherwise poor leaving group such as $-OH$.

Remark 1.9 (Good leaving group). Recall that **weaker bases are better leaving groups**. One has to look how could the leaving group stabilize / balance the negative charge: **Inorganic orthophosphate** (the ionized form of H_3PO_4 at neutral pH, a mixture of $H_2PO_4^-$ and HPO_4^{2-} , commonly abbreviated as P_i) and inorganic pyrophosphate ($P_2O_7^{4-}$, abbreviated as PP_i); **esters and anhydrides of phosphoric acid** and **thiols** are also good leaving groups.

(a) Nucleophilic substitution

(b) Relative reactivity of carboxylic acid derivatives

Figure 4: Group Transfer Reactions

1.2.0.5 Oxidation-Reduction Reactions

Carbon atoms can only exist in five oxidation states, depending on their binding partners. Note that **carbon is less electronegative than all atoms it is bound to, except hydrogen**. Thus all atoms that bind to carbon oxidize it except hydrogen and therefore removing a hydrogen and replacing that bond with any other atom (including carbon) is synonymous with oxidation. Recall that every oxidation must be linked to a reduction. Note that, **Oxidations generally release energy** (camp fires where wood is oxidized).

Often in biological oxidations, a compound loses two electrons and two hydrogens (2 hydrogen atoms), these reactions are called **dehydrogenations** catalyzed by **Dehydrogenase**.

Sometimes in biological oxidations a carbon becomes covalently bounded to an oxygen. The corresponding enzymes are called **Oxidase** and if the oxygen atom is derived from molecular oxygen they are called **Oxygenase**.

(a) The 5 oxidation levels of carbons

(b) lactate dehydrogenase

Figure 5: Oxidation-Reduction Reactions

1.3 Phosphoryl and ATP fun

In a phosphate transfer reaction, a phosphate group is transferred from a phosphate group donor molecule to a phosphate group acceptor molecule.

1.3.0.1 Phosphate groups

Recall some important properties of phosphorus from organic chemistry:

- Phosphates are **excellent leaving groups** in biological organic reactions, which can be seen for example in the hydrolysis of ATP.
- Phosphoric acid (H_3PO_4) is triprotic, meaning that it has three acidic protons available to donate with pK_a values of 1, 6.5, 13, respectively.
- Phosphorus can break the octet rule because it is in the third row of the periodic table and thus has **d orbitals** available for bonding.
- The phosphate group is really tetrahedral, the **negative charges are delocalized** over the non-bridging oxygens, and there is some degree of protonation at physiological pH (with the exception of the phosphate di-ester group.)

Phosphate transfer enzymes generally contain a **Mg^{2+} ion bound in the active site** in a position where it can interact with non-binding phosphate oxygens on the substrate. This magnesium ion pulls the electron density away from the phosphorus atom, making it more electrophilic.

A phosphate transfer reaction can be thought of as a $\text{S}_\text{N}2$ reaction at a carbon center. Recall that the phosphorus can form a **"5-bond" transition state**.

1.3.0.2 The phosphate enzymes

Definition 1.10 (Kinases). *Kinase (from Greek *kinein*, "to move") is an enzyme that catalyzes the transfer of phosphate groups from high-energy donor molecules, such as ATP, to specific substrates, a process known as phosphorylation.*

Definition 1.11 (Phosphatases). *Phosphatase is an enzyme that removes phosphate groups from proteins or other molecules, a process known as dephosphorylation, which often regulates cellular activity.*

Remark 1.12 (Reactions catalyzed by kinases and phosphatases are not the reverse of one another). Kinases irreversibly transfer phosphate groups from ATP (or sometimes other nucleoside triphosphates) to various organic acceptor compounds, while phosphatases transfer phosphate from organic compounds to water: this are hydrolysis reactions. Kinase reactions involve an inherently "uphill" step (phosphorylation of alcohols for example) being paid with an inherently "downhill" step (cleavage of an anhydride bond in ATP). Phosphatase reactions, on the other hand, are thermodynamically "downhill", and while they require an enzyme to speed them up, they do not involve "spending" energy current the way kinases do.

1.3.0.3 ATP

ATP (Adenosine Triphosphate) is the **energy currency** of the cell and links catabolism and anabolism. ATP is a high energy compound which can be seen when considering hydrolysis of ATP (highly exergonic), since:

- Hydrolysis relieves electrostatic repulsion between the negatively charged phosphates. One way to picture this is **acoil springing open, releasing potential energy**
- Inorganic phosphate can be stabilized by resonance hybrid.
- ADP-2 can ionize

- The products are better solvated than the reactants.

Note: that ATP-cleaving reaction are exothermic, but also have a high energy barrier, making it them very slow unless catalyzed by an enzyme. This helps us gain a tight control over the reactions in our metabolic pathways.

ATP provide energy by transferring its phosphate group and not by mere hydrolysis. Nevertheless often we say that a given reaction is coupled to ATP hydrolysis which provides the energy required for the reaction to happen. Note that **ATP hydrolysis per se only provides heat.**

In many reactions **ATP is used as a phosphate donor** to a substrate that, once phosphorylated, acquires an higher free energy.

Figure 6: ATP

Note: To maintain its high group transfer potential, ATP concentration must be held far above the equilibrium concentration by energy-yielding reactions of catabolism.

Moreover, inorganic polyphosphate, present in all cells, may serve as a reservoir of phosphoryl groups with high group transfer potential.

To produce ATP we need higher energy compounds. Cells contain other metabolites with large, negative, free energies of hydrolysis, including phosphoenolpyruvate, 1,3-bisphosphoglycerate, and phosphocreatine. These high-energy compounds, like ATP, have a high phosphoryl group transfer potential. Thioesters also have high free energies of hydrolysis.

Figure 7: Hydrolysis of Phosphate compounds

Remark 1.13 (Arsenate Poisoning). A toxic condition caused by exposure to arsenate (AsO_4^{3-}), which disrupts cellular metabolism by **mimicking inorganic phosphate**. Arsenate can uncouple oxidative phosphorylation by substituting for inorganic phosphate oxidative pathways, ATP synthesis, leading to decreased ATP production and cellular toxicity.

For example In the presence of arsenate, the product of glyceraldehyde 3-phosphate dehydrogenase is 1-arseno-3-phosphoglycerate, which nonenzymatically decomposes to 3-phosphoglycerate and arsenate; this substrate for the phosphoglycerate kinase is therefore bypassed, which leads in no net glycolytic synthesis of ATP.

1.4 Biological Oxidation-Reduction Reactions

Since we need high energy compounds to produce ATP. We have to ask us but how do we produce these Hi-NRG (NRG = energy)? **-The flow of electrons can do it!**

Definition 1.14 (Electromotive force (emf)). *Electrons flow from a reducing agent to an oxidizing agent due to their different electron affinities. This difference in affinities is called the electromotive force. Note that the reducing agent undergoes oxidation and the oxidizing agent undergoes reduction.*

Note, that **living cells have an biological "circuit", with a relatively reduced compound such as glucose as the source of electrons**. As glucose is enzymatically oxidized, the released electrons flow spontaneously through a series of electron-carrier intermediates to another chemical species, such as O_2 . This **electron flow is exergonic**, because O_2 has a higher affinity for electrons than do the electron-carrier intermediates. This is exploited by the **ATP synthase** in the inner mitochondrial membrane that uses the proton-motive force to do chemical work.

1.4.0.1 Dehydrogenation = Oxidation

Dehydrogenation corresponds to oxidation, since the carbon is less electronegative than all atoms it is bound to except hydrogen. *Note that not all oxidation-reduction reactions involve carbon, i.e conversion from nitrogen to ammonia.*

There are different types electrons can be transferred: Directly as electrons, As hydrogen atoms, as a hydrogen ion or through direct combination with oxygen. Since all of this 4 types occur biologically the term **Reducing Equivalent** is used.

Figure 8: Oxidation levels of a carbon compound in the biosphere

1.5 Electron Carriers

There are a multitude of enzymes that catalyze oxidation reactions from a variety of substrates, but most electrons end up in a **small set of univale electron carriers**, such as NAD^+ , FAD , and Q (ubiquinol).

Definition 1.15 (Electron Carriers). *Electron Carrier are Molecules that can accept and donate electrons, facilitating the transfer of energy in redox reactions (e.g., NAD^+ , FAD).*

1.5.0.1 NADH and NADPH

These **watersoluble** coenzymes (NAD^+ (Nicotinamide Adenine Dinucleotide) and $NADP^+$ (Nicotinamide Adenine Dinucleotide Phosphate)) can undergo **reversible reduction of the necotinamide ring**, as a substrate undergoes oxidation (dehydrogenation) giving up **2 hydrogen atoms**.

- NAD^+ and $NADP^+$ take **2 electrons and 1 proton** while the second proton is released into solution.

In many cells and tissues, the ratio of NAD^+ (oxidized) to $NADH$ (reduced) is high, favoring hydride transfer from a substrate to NAD^+ to form $NADH$. By contrast, $NADPH$ is generally present at a higher concentration than $NADP^+$, favoring hydride transfer from $NADPH$ to a substrate.

This reflects the specialized metabolic roles of the two coenzymes: **NAD^+ generally functions in oxidations—usually as part of a catabolic reaction; $NADPH$ is the usual coenzyme in reductions—nearly always as part of an anabolic reaction.**

Figure 9: NADH and NADPH

Remark 1.16 (Dietary Deficiency of Niacin (Vitamin B3) cause Pellagra). NAD and NADP are derived from the Niacin (Vitamin B3)), which is synthesized from tryptophan. Humans do generally not synthesize sufficient quantities of niacin, and this is especially so for individuals with diets low in tryptophan (diets based on maize for example). This leads to the disease pellagra.

But note since NAD⁺ can oxidize many thousands of molecules of glucose, since its reduction always can be reversed. It is not necessary to consume a lot of the vitamin, in contrast to glucose for example.

1.5.0.2 FAD and FMN

FAD (Flavin Adenine Dinucleotide) and FMN (Flavin Mononucleotide) are coenzymes that are used in oxidation-reduction reactions by **Flavoprotein**. They are **tightly bound to their enzymes**, in contrast to NAD and NADP. Moreover, because flavin nucleotides can also only take on one electron and one proton in the partially reduced form.

- FAD and FMN take **1 or 2 electrons and 1 or 2 protons** and remain tightly linked to the enzyme.

Moreover, because flavin nucleotides can also **only one electron and one proton** in the partially reduced form. This is important since FAD and FMN are **key in electron transport reactions** (e.g. **ETC Complex I and II**), where electrons are passed one at a time.

Figure 10: Flavin Nucleotides

These Flavin nucleotides are derived from the **vitamin riboflavin (B2)**

1.5.0.3 Ubiquinone, Q

Ubiquinone (Coenzyme Q) is a **lipid-soluble** electron carrier in the electron transport chain, transferring electrons between complex I/II and complex III. Ubiquinone exists in oxidized (Q), semiquinone (Q^-), and reduced (QH_2) forms.

2 Metabolism

Metabolism is the sum of all biochemical reactions in a living organism. The metabolism can be divided into two main pathways: catabolism and anabolism.

2.1 Catabolism \rightleftharpoons Anabolism

Catabolism from greek meaning "**breaking down**" (Kata refers to down and bolē means to throw) is the process of breaking down complex molecules into simpler ones, **releasing/ producing energy in the form of ATP**. Examples include glycolysis, the Krebs cycle, and oxidative phosphorylation, which break down glucose and fatty acids to produce ATP. *Note this catabolic pathways are mostly **converging***

In contrast, **Anabolism** from Greek meaning "**building up**" (Ana means up or again) is the synthesis of complex molecules from simpler ones, **requiring energy**. This process is essential for growth, repair, and maintenance of cells. Examples include protein synthesis, DNA replication, and lipid biosynthesis. *Note this anabolic pathways are mostly **diverging***

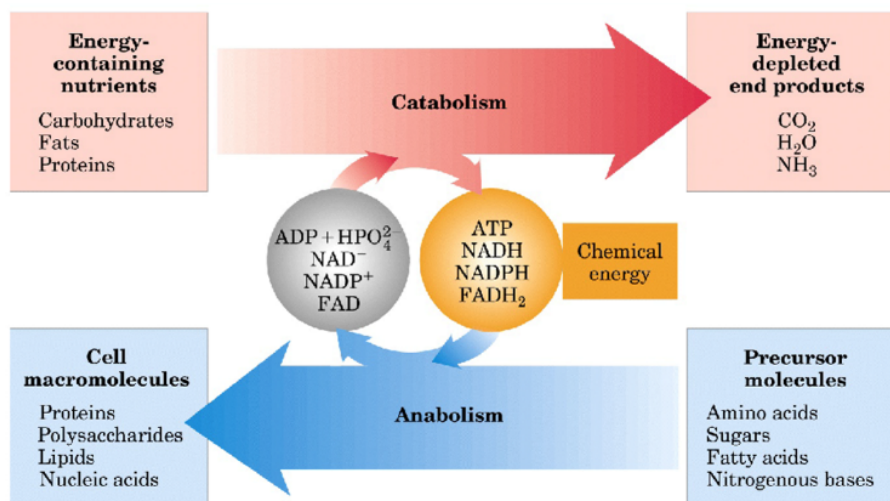

Figure 11: Catabolism \rightleftharpoons Anabolism

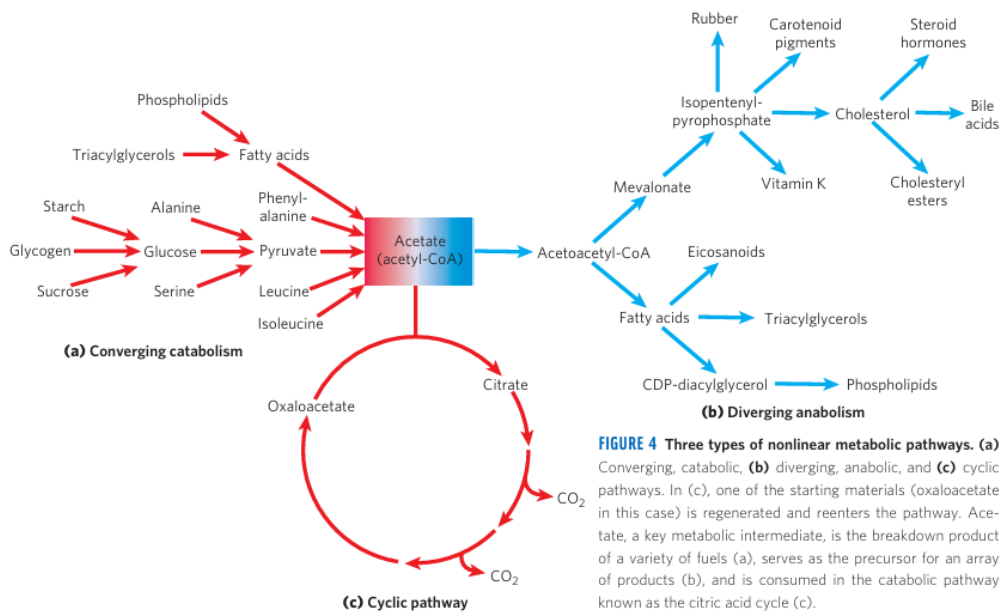

Figure 12: Three types of nonlinear metabolic pathways

2.2 Thermodynamic in Biological pathways

Definition 2.1 (The second law of thermodynamics). *The Second Law of Thermodynamics states that the total entropy of an isolated system can never decrease over time. Isolated systems spontaneously evolve toward thermodynamic equilibrium, the state with the **maximum Entropy**.*

In a **chemical reaction** entropy increases when the products of the reaction are less complex and more disordered than its substrates. Therefore in many biochemical reactions seem to contradict the second law as they "produce order"

To compensate the produced order by cells in their growth and division **free energy** is taken from the environment in the form of nutrients or solar light and exchanged for heat and entropy.

Definition 2.2 (Free energy (G)). *In biochemistry, Gibbs free energy (G) determines whether a metabolic reaction "can occur spontaneously" (but may still be unlikely because of TS) in living systems. A process is favorable if it is **Exergonic Reaction**, $\Delta G < 0$.*

It represents the energy available to do biological work, such as muscle contraction, active transport, and biosynthesis. The change in Gibbs free energy (ΔG) for a reaction is given by:

$$\Delta G = \Delta H - T\Delta S$$

An important property is that variations in delta G are **additive**:

$$\Delta G_{\text{total}} = \Delta G_1 + \Delta G_2$$

This property lets us **make unfavorable reaction favorable when coupling them to a highly favorable reaction**. These **Coupled Reactions** are explored by various biological pathways.

3 Anabolism

3.1 Glycolysis

D-Glucose is the major nutrient for a wide range of organisms. It can be stored by cells in the form of polymers and used upon need to generate ATP.

In glycolysis (from the Greek *glycus*, "sugar", and *lysis*, "splitting") a molecule of **glucose** is degraded in a series of enzyme-catalyzed reactions to **two** molecules of **pyruvate**.

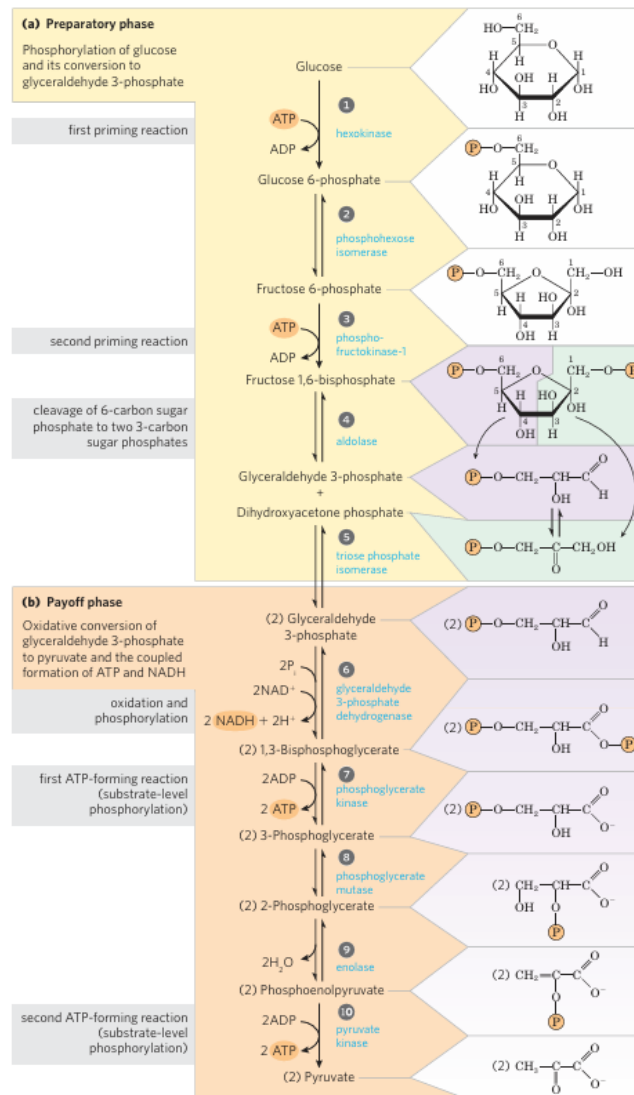

Figure 13: Glycolysis

3.1.0.1 Carbon labeling

Note when labeling GA3P the number do not correspond to the same numbers from the fructose compound. *One always follows the normal rules*

Figure 14: Carbon labeling

Glycolysis can be divided into two stages: the preparation phase and the payoff phase.

3.1.1 Stage 1, Preparation Phase

In the preparation phase, glucose gets **trapped** inside the cell, **"activated"**, and **broken down** into smaller components.

3.1.1.1 Step 1: Phosphorylation of Glucose

D-Glucose moves into the cell with the help of a **membrane transporter**. Once in the cytoplasm, it undergoes phosphorylation by **hexokinase** to produce **Glucose 6-phosphate**. This has two consequences:

- **No backsies:** Glucose 6-phosphate is structurally different and thus can not be transported out by the same membrane transporter.
- **More reactive:** The substitution of the hydroxy group with the phosphate group (2 additional charges, etc.) makes the molecule more reactive. But this has to be paid by the **investment** of 1 ATP molecule.

Figure 15: Phosphorylation of Glucose

Remark 3.1 (Hexokinase (HK)). Hexokinase is an enzyme that phosphorylates hexoses (like glucose) using ATP. Like most kinases it requires the presence of the cofactor Mg^{2+} in the active site.

The movement of Glucose into HK active site causes a conformational change whereby two HK lobes rotated by 12 degrees (10°) creating an **induced fit**. This makes the **carbon 6 oriented towards ATP** and squeezes out water molecules. (see fig. 15(b))

3.1.1.2 Step2: Isomerization

In the second step the enzyme **phospho-glucose isomerase** transforms aldose (Glucose) into ketose (Fructose). This is done in order to create more symmetry preparing step 3.

Figure 16: Isomerization

3.1.1.3 Step3: Second phosphorylation

The enzyme **phospho-fructo kinase-1 (PFK-1)** turns Fructose 6-phosphate into Fructose 1,6-bisphosphate, completing the symmetry and making the compound even more reactive. This is again paid with the **investment of 1 ATP**. (see fig. 17(a))

Note, that **this step commits the sugar to glycolysis**. This is why **PFK-1 is a highly regulated enzyme** where its activity is modified according to cellular concentration of ATP, ADP, and AMP. (**ATP inhibits - AMP stimulates**).

3.1.1.4 Step4: Breakdown of Fructose 1,6-bisphosphate

Aldolase catalyses the breakdown of Fructose 1,6-bisphosphate into 2 different three-carbon molecules (**GA3P and DHAP**). GA3P feeds directly in the glycolytic pathway without any further change while DHAP needs

Figure 17: Step3 and Step4

to be first transformed. This is achieved by Step5.

3.1.1.5 Step5: Isomerisation of DHAP to GA3P

Triose phosphate isomerase (TPI or TIM) catalyses the rapid and reversible conversion of DHAP to GA3P, ketone to aldehyde. This happens via an intramolecular redox reaction where **an hydrogen is transferred from C1 to C2**.

Figure 18: Isomerisation of DHAP to GA3P

Even though TPI increases the rate by 10 billion fold the equilibrium still lies on the unwanted side of DHAP (the **reaction is unfavorable**). But since the reaction is coupled to endergonic reactions (GA3P is always directly used), the reaction shifts to the side of the product GA3P.

3.1.2 Stage2, Payoff Phase

In the payoff phase the components from the stage 1 get **oxidized** in order to produce ATP, NADH, and pyruvate.

3.1.2.1 Step6: Conversion of GA3P to 1,3-BPG

GA3P is converted into 1,3-biphosphoglycerate (1,3-BPG) by the enzyme glyceraldehyde 3-phosphate **dehydrogenase (GAPDH)**. Note this reaction produces NADH, which can later be oxidized.

Figure 19: Conversion of GA3P to 1,3-BPG

3.1.2.2 Step7: Phosphotransfer from 1,3-BPG to ADP

Step7 is the **break-even point**. 1, 3-BPG is used as a phosphate donor to ADP. This reaction is catalyzed by **glycerophosphate kinase** and produces 3-Phosphoglycerate and ATP. (see fig. 20(a))

3.1.2.3 Step8: Conversion to 2-Phosphoglycerate

Phosphoglycerate mutase catalyses the transfer of the phosphate group from C3 of 3-phosphoglycerate to C2 to form 2-phosphoglycerate.

Figure 20: Step7 and Step8

3.1.2.4 Step9: Conversion to Phosphoenolpyruvate (PEP)

Enolase converts 2-phosphoglycerate into phosphoenolpyruvate (PEP). This **dehydration reaction** increases the **phosphoryltransfer potential** of the molecule.

3.1.2.5 Step10: Conversion to Pyruvate

The phosphoryltransfer potential of **PEP** is exploited to create ATP and pyruvate. The enzyme **pyruvate kinase** catalyses the phosphoric transfer. At this point we have gained a **total of 2 ATP and 2 NADH**.

Figure 21: Step9 and Step10

3.1.3 The fates of Pyruvate

Pyruvate is a three-carbon molecule that is the end product of glycolysis.

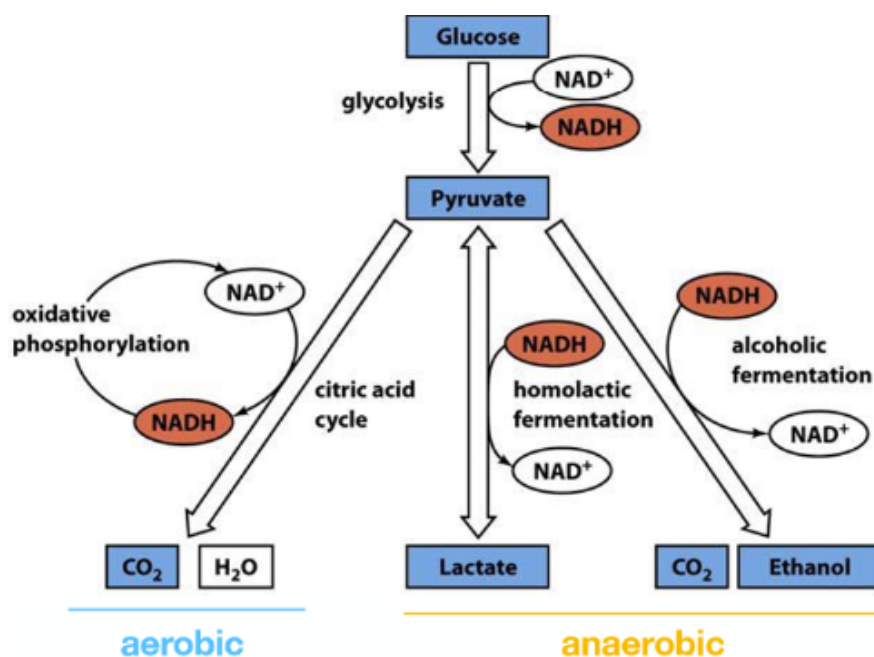

Figure 22: The fates of Pyruvate

Definition 3.2 (Facultative Anaerobic Organism). A Facultative Anaerobic Organism is able to produce ATP by anaerobic respiration if oxygen is present, but is also capable of switching to fermentation if oxygen is absent. For example *E.coli* or some muscle cells (temporarily in humans).

Remark 3.3 (Soy Sauce). Soy sauce is produced by fermenting a salted mixture of soy beans. Soybeans contain starch which will be broken down to glucose and then degraded via glycolysis to pyruvate. And the fermented in the absence of oxygen. However if oxygen were present pyruvate would be oxidized to acetyl-CoA entering the citric acid cycle. But some acetyl-CoA would get hydrolyzed to acetic acid (vinegar) which would result in a undesired strong vinegar taste.

3.1.3.1 Ethanol Fermentation

Yeast and several bacteria utilise ethanol (alcoholic) fermentation to regenerate NAD⁺ and to transform pyruvate into ethanol and carbon dioxide.

In a first step **pyruvate decarboxylase** catalyses a decarboxylation reaction. The enzymes needs the **coenzyme TPP**, a vitamin B1 derivative, and cofactor Mg^{2+}

- Note, that the **C3 & C4 carbons of glucose will be cut away** in form of CO_2 .

In the second step **alcohol dehydrogenase** will regenerate NAD^+ in reducing acetaldehyde to ethanol. Note alcohol dehydrogenase contains a **zinc ion** in the active site to help polarize the carbonyl double bond that promotes hydride transfer from $NADH$.

Figure 23: Ethanol Fermentation

- $Glucose + 2ADP + 2P_i \Rightarrow 2\text{ Ethanol} + 2ATP + 2CO_2 + 2H_2O$

3.1.3.2 Lactic Fermentation

Many **prokaryotic and eukaryotic** organisms can use lactic fermentation. Like ethanol fermentation it is necessary to **regenerate NAD^+** . Lactic fermentation is catalysed by **lactate dehydrogenase (LHD)**.

Figure 24: Lactic Fermentation

Remark 3.4 (Cancer, PET scan). Cancer cells often rely on aerobic glycolysis, known as the **Warburg effect**, where they preferentially use glycolysis followed by lactic acid fermentation, even in the presence of oxygen. This allows them to rapidly generate ATP and biosynthetic precursors for growth.

Positron Emission Tomography (PET scans) exploit this metabolic shift by using **fluorodeoxyglucose (FDG)**, a radiolabeled glucose analog. Since cancer cells have a higher glucose uptake due to increased glycolysis, they accumulate FDG, which emits positrons detectable by **PET imaging**.

3.2 TCA cycle

3.3 Fatty Acid Oxidation

3.4 Amino Acid Oxidation

Glossary

Anabolism Metabolic pathways that build complex molecules from simpler ones, requiring an input of energy.. 11

Arsenate Poisoning A toxic condition caused by exposure to arsenate (AsO_4^{3-}), which disrupts cellular metabolism by mimicking phosphate. Arsenate can uncouple oxidative phosphorylation by substituting for inorganic phosphate glycolysis or ATP synthesis, leading to decreased ATP production and cellular toxicity. Symptoms include nausea, vomiting, neurological disturbances, and multi-organ failure in severe cases.. 8

ATP (Adenosine Triphosphate) The primary energy currency of the cell, used to power many cellular processes. Its hydrolysis releases heat but not energy, while the transfer of phosphate leads to a higher state in free energy of the substrate.. 6

Catabolism Metabolic pathways that break down complex molecules into simpler ones, releasing energy.. 11

Coupled Reactions Two chemical reactions linked together, where an energetically favourable reaction (e.g., ATP hydrolysis) provides the energy to drive an energetically unfavourable reaction.. 12

Dehydrogenase An enzyme that catalyzes the removal of two hydrogen atoms from a substrate, typically transferring them to an electron acceptor such as NAD^+ or FAD. Dehydrogenases play a crucial role in metabolic pathways like glycolysis and the citric acid cycle.. 5

Electron Carrier Molecules that can accept and donate electrons, facilitating the transfer of energy in redox reactions (e.g., NAD^+ , FAD).. 9

Enthalpy (H) A thermodynamic quantity representing the total heat content of a system. In biochemistry, enthalpy changes (ΔH) are associated with bond formation and breaking, influencing biochemical reactions and energy transfer.. 1

Entropy A measure of the disorder or randomness of a system. The second law of thermodynamics states that the total entropy of an isolated system tends to increase over time.. 1, 12

Exergonic Reaction A chemical reaction that releases energy (has a negative ΔG) and is therefore favorable. . 1, 12

Facultative Anaerobic Organism A organism that is able to produce ATP by anerobic respiration if oxygen is present, but is also capable of switching to fermentation if oxygen is absent. 18

FAD (Flavin Adenine Dinucleotide) A redox-active coenzyme associated with various enzymes, particularly in the electron transport chain and fatty acid oxidation. FAD is reduced to FADH_2 , which donates electrons to the respiratory chain.. 10

Flavoprotein A protein that contains a flavin coenzyme, such as FAD or FMN, as a prosthetic group. 10

FMN (Flavin Mononucleotide) A coenzyme derived from riboflavin (vitamin B2) that acts as a prosthetic group in various oxidoreductases, including NADH dehydrogenase in the electron transport chain. FMN is involved in redox reactions, cycling between oxidized and reduced states.. 10

Hexokinase An enzyme that catalyzes the phosphorylation of glucose to glucose-6-phosphate, the first step in glycolysis.. 15

Kinase An enzyme that catalyzes the transfer of phosphate groups from high-energy donor molecules, such as ATP, to specific substrates, a process known as phosphorylation.. 6

NAD⁺ (Nicotinamide Adenine Dinucleotide) A coenzyme involved in redox reactions, serving as an electron carrier in cellular respiration. NAD⁺ is reduced to NADH, which donates electrons to the electron transport chain for ATP production.. 9

NADP⁺ (Nicotinamide Adenine Dinucleotide Phosphate) A phosphorylated form of NAD⁺ that functions as an electron carrier, primarily in anabolic pathways such as fatty acid and nucleotide biosynthesis. NADP⁺ is reduced to NADPH, which provides reducing power for biosynthetic reactions.. 9

Niacin (Vitamin B3) A water-soluble B vitamin essential for energy metabolism, DNA repair, and cell signaling. Niacin is a precursor to the coenzymes NAD⁺ and NADP⁺, which are crucial for redox reactions in cellular respiration and biosynthetic pathways. 10

Oxidase An enzyme that catalyzes oxidation reactions, using molecular oxygen (O₂) as the electron acceptor without incorporating it into the substrate. Oxidases are involved in various biological oxidation processes, including those in the electron transport chain.. 5

Oxygenase An enzyme that catalyzes the incorporation of oxygen atoms from molecular oxygen (O₂) into a substrate. Oxygenases are classified into monooxygenases and dioxygenases, which incorporate one or two oxygen atoms, respectively, and are essential in metabolic pathways like drug metabolism and biosynthesis.. 5

Phosphatase An enzyme that removes phosphate groups from proteins or other molecules, a process known as dephosphorylation, which often regulates cellular activity.. 6

Pyruvate A three-carbon molecule that is the end product of glycolysis.. 18

Reducing Equivalent A unit of reducing power in biochemical redox reactions, referring to the transfer of one electron (or its equivalent as a hydrogen atom or hydride ion). Reducing equivalents are carried by molecules such as NADH, NADPH, and FADH₂, playing a crucial role in cellular respiration and biosynthetic pathways.. 9

Second Law of Thermodynamics States that the total entropy of an isolated system can never decrease over time.. 1, 12

Ubiquinone (Coenzyme Q) A lipid-soluble electron carrier in the electron transport chain, transferring electrons between complex I/II and complex III. Ubiquinone exists in oxidized (Q), semiquinone (Q⁻), and reduced (QH₂) forms.. 11
